Toxic epidermal necrolysis

Part I. Introduction, history, classification, clinical features, systemic manifestations, etiology, and immunopathogenesis

Robert A. Schwartz, MD, MPH, DSc (Hon), FRCP (Edin), Patrick H. McDonough, MD, and Brian W. Lee, MD, MS
Newark, New Jersey

CME INSTRUCTIONS

The following is a journal-based CME activity presented by the American Academy of Dermatology and is made up of four phases:

1. Reading of the CME Information (delineated below)
2. Reading of the Source Article
3. Achievement of a 70% or higher on the online Case-based Post Test
4. Completion of the Journal CME Evaluation

CME INFORMATION AND DISCLOSURES

Statement of Need:
The American Academy of Dermatology bases its CME activities on the Academy's core curriculum, identified professional practice gaps, the educational needs which underlie these gaps, and emerging clinical research findings. Learners should reflect upon clinical and scientific information presented in the article and determine the need for further study.

Target Audience:
Dermatologists and others involved in the delivery of dermatologic care.

Accreditation
The American Academy of Dermatology is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians.

AMA PRA Credit Designation
The American Academy of Dermatology designates this journal-based CME activity for a maximum of 1 *AMA PRA Category 1 Credits*™. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

AAD Recognized Credit
This journal-based CME activity is recognized by the American Academy of Dermatology for 1 AAD Credit and may be used toward the American Academy of Dermatology's Continuing Medical Education Award.

Disclaimer:
The American Academy of Dermatology is not responsible for statements made by the author(s). Statements or opinions expressed in this activity reflect the views of the author(s) and do not reflect the official policy of the American Academy of Dermatology. The information provided in this CME activity is for continuing education purposes only and is not meant to substitute for the independent medical judgment of a healthcare provider relative to the diagnostic, management and treatment options of a specific patient's medical condition.

Disclosures

Editors
The editors involved with this CME activity and all content validation/peer reviewers of this journal-based CME activity have reported no relevant financial relationships with commercial interest(s).

Authors
The authors of this journal-based CME activity have reported no relevant financial relationships with commercial interest(s).

Planners
The planners involved with this journal-based CME activity have reported no relevant financial relationships with commercial interest(s). The editorial and education staff involved with this journal-based CME activity have reported no relevant financial relationships with commercial interest(s).

Resolution of Conflicts of Interest
In accordance with the ACCME Standards for Commercial Support of CME, the American Academy of Dermatology has implemented mechanisms, prior to the planning and implementation of this Journal-based CME activity, to identify and mitigate conflicts of interest for all individuals in a position to control the content of this Journal-based CME activity.

Learning Objectives
After completing this learning activity, participants should be able to delineate the drugs that are a common cause of toxic epidermal necrolysis (TEN); list the human leukocyte antigen allotypes associated with TEN and that engender an increased risk of TEN caused by drugs including allopurinol and aromatic anticonvulsant agents; and differentiate TEN from milder drug eruptions.

Date of release: August 2013
Expiration date: August 2016

Toxic epidermal necrolysis is a life-threatening, typically drug-induced mucocutaneous disease. It is clinically characterized as a widespread sloughing of the skin and mucosa, including both external and internal surfaces. Histologically, the denuded areas show full thickness epidermal necrosis. The pathogenic mechanism involves antigenic moiety/metabolite, peptide-induced T cell activation, leading to keratinocyte apoptosis through soluble Fas ligand, perforin/granzyme B, tumor necrosis factor—alfa, and nitric oxide. Recent studies have implicated granulysin in toxic epidermal necrolysis apoptosis and have suggested that it may be the pivotal mediator of keratinocyte death. (J Am Acad Dermatol 2013;69:173.e1-13.)

Key words: apoptosis; drug eruption; erythema multiforme; granulysin; Stevens—Johnson syndrome; toxic epidermal necrolysis.

TOXIC EPIDERMAL NECROLYSIS

- **Toxic epidermal necrolysis is most commonly caused by drugs and begins with a prodrome of fever, anorexia, pharyngitis and morbilliform rash**
- **Toxic epidermal necrolysis is a systemic disease involving the ophthalmic, pulmonary, genitourinary, and gastrointestinal systems, in addition to the skin**

CAPSULE SUMMARY

- Toxic epidermal necrolysis is characterized by widespread sloughing of the skin and the mucosal surface of the oral cavity, gut, kidneys, eye, genitalia, and/or lungs.
- The mechanism of cell death is apoptosis via drug-induced $CD8^+$ cell exocytosis of granzyme B/perforin and granulysin and through the activation of the Fas—Fas ligand pathway and tumor necrosis factor—alfa/death receptor pathway.
- The pathogenesis of toxic epidermal necrolysis is initiated either by noncovalent, direct interaction of a drug antigenic moiety with a specific major histocompatibility complex I allotype or by covalent binding of a drug metabolite to a cellular peptide to form an immunogenic molecule.
- Certain human leukocyte antigen allotypes are associated with toxic epidermal necrolysis and engender an increased risk of toxic epidermal necrolysis caused by drugs including allopurinol and aromatic anticonvulsant agents.

Toxic epidermal necrolysis (TEN) is an acute life-threatening mucocutaneous disorder that has an estimated incidence of 0.4 to 1.9 per million people annually worldwide.[1-3] The overall combined incidence of Stevens—Johnson syndrome (SJS), SJS/TEN overlap, and TEN is estimated to be 2 to 7 per million cases per year.[4-8] SJS has an annual incidence of 1.2 to 6 per million people,[9] approximately outnumbering TEN threefold. Studies have shown a thousand-fold increase in the incidence of SJS and TEN among those with an HIV infection, which is estimated at 1 in 1000.[10] A multicenter study from sub-Saharan Africa, where there is a high prevalence of HIV, confirmed the association between SJS/TEN and HIV and revealed an association with a high frequency of antiretroviral drug use.[11]

TEN occurs in all age groups, with 1 case described in a fetus, and is more frequently found in women and the elderly.[7,12-14]

HISTORY

- **Toxic epidermal necrolysis is most commonly caused by drugs and begins with a prodrome. It is also known as Lyell syndrome, which was first delineated by Alan Lyell in 1956**

In 1939, Debre et al[15] first described a case that appeared to be TEN. The name TEN was proposed by Lyell[16] in 1956 after he recognized "a toxic eruption, which closely resembles scalding" in 4 patients, 1 of whom was later reclassified as having staphylococcal scalded skin syndrome.[17] SJS was first reported in 2 pediatric patients as a "new eruptive fever associated with stomatitis and ophthalmia" in 1922 by 2 American physicians, Albert Mason Stevens and Frank Chambliss Johnson.[18] Erythema multiforme (EM) was first described by von Hebra in 1862 as mild, self-limited eruption caused by a herpes simplex virus (HSV) infection.[9,19]

Abbreviations used:

ALDEN:	algorithm for drug causality for epidermal necrolysis
APC:	antigen presenting cell
BSA:	body surface area
CD40L:	CD40 ligand
EM:	erythema multiforme
FasL:	Fas ligand
HLA:	human leukocyte antigen
MHC:	major histocompatibility complex
NF-κB:	nuclear factor kappaB
NK:	natural killer
NO:	nitric oxide
PBMC:	peripheral blood mononuclear cell
sFasL:	serum Fas ligand
SJS:	Stevens–Johnson syndrome
TEN:	toxic epidermal necrolysis

CLASSIFICATION

- **While Stevens–Johnson syndrome and toxic epidermal necrolysis may well be variants of the same spectrum of disease, differing by the severity of body surface area affected, some experts believe that they are etiologically and pathologically distinct diseases**
- **Stevens–Johnson syndrome may be defined by the involvement of ≥2 mucous membranes or by the relatively smaller percentage of body surface area affected when compared to toxic epidermal necrolysis**

The categorization of EM, SJS, and TEN remains a topic of ongoing controversy because of the incomplete elucidation of pathogenic mechanisms. There are differing opinions on the classification of EM major and SJS as well as SJS and TEN. Based on similar histologic findings, SJS has been synonymously associated with EM major since 1983[20]—both feature the involvement of ≥2 mucous membranes in addition to skin lesions. Bastuji-Garin et al[21] in 1993 and Roujeau et al[22] in 1994 proposed differentiation of the two based on clinical and etiologic information[23]: EM major is characterized by acrally distributed typical targets related to mycoplasma infection. SJS consists of widespread blisters caused by a drug reaction, arising on erythematous or purpuric macules predominantly located on face and trunk. In contrast, TEN and SJS, initially described as separate entities, gradually have been unified as aspects of a spectrum within the same entity based on similar clinical and histopathologic features with variable severity in epidermal detachment.[21]

EM minor, EM major, SJS, and TEN share many features and were once considered to be in the same spectrum of reactive skin disorders.[24] EM is now regarded to be a separate condition with clinical, epidemiologic, and etiologic characteristics distinct from those of SJS and TEN.[25] Bastuji-Garin et al[21] proposed SJS, SJS/TEN overlap, and TEN as classifications based on severity of epidermal detachment. This classification system divides the spectrum of these reactive skin disorders into 5 categories: (1) EM major—detachment of <10% of BSA plus localized target lesions; (2) SJS—detachment of <10% of BSA plus widespread erythematous or purpuric macules or flat atypical target lesions; (3) overlapping SJS/TEN—detachment between 10% and 30% of BSA plus widespread erythematous or purpuric macules or atypical target-like annular patches; (4) TEN with spots—detachment of >30% of BSA plus widespread erythematous or purpuric macules or atypical target lesions; and (5) TEN without spots—detachment in large epidermal sheets >10% BSA without purpuric macules or target lesions.[21] We believe that SJS, SJS/TEN overlap, and TEN are variants of the same entity, but this classification scheme is imperfect because it does not take into account the differences in etiologies of these diseases.

CLINICAL FEATURES

- **Drug reactions are responsible for 80% to 95% of cases of toxic epidermal necrolysis, which involves epidermal sloughing of >30% of the body surface area**
- **Toxic epidermal necrolysis may be morbilliform, defined as a fine, discrete maculopapular exanthem, or consist of atypical targetoid macules**
- **Nearly all patients with toxic epidermal necrolysis have flaccid bullae, skin erosions, and painful inflammation and ulceration in the oral cavity over the span of 1 day to 2 weeks**

Clinically, EM should be differentiated from SJS/TEN. EM is a self-limited condition associated with mild or no systemic involvement. It is characterized by the pathognomonic "target" lesions with 3 concentric zones: a central dusky/dark red area, a paler pink/edematous zone, and a peripheral red ring. "Atypical papular lesions" have round, edematous, palpable lesions with only 2 zones and/or poorly defined borders.[24,26] EM is symmetrically distributed on the distal extremities with minimal epidermal detachment, often to 1% or 2% of BSA (<10% of BSA).[27,28] Various mucosal site involvement is observed in EM, SJS, and TEN (25-60% for EM, with minimal mucosal involvement for EM minor; 92-100% of patients for SJS; and nearly all patients for TEN).[26,29-31]

TEN displays denudation of the epidermis in sheets during the acute phase (Figs 1-3). SJS is characterized by confluent purpuric macules or

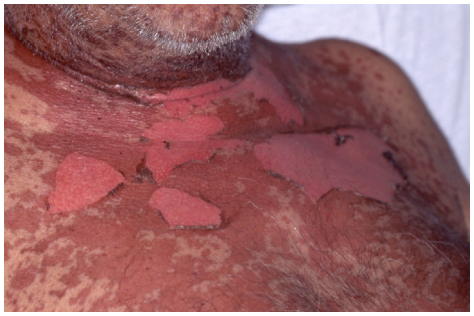

Fig 1. Toxic epidermal necrosis. Patient with denudation of the epidermis in sheets resembling wet cigar paper. Note the widespread involvement of the trunk.

Fig 2. Toxic epidermal necrosis. Patient with denudation of the epidermis in sheets resembling wet cigar paper. Note the widespread involvement of the right upper extremity.

atypical flat targetoid lesions, with blisters and erosions covering <10% of BSA, 10% to 30% of BSA for SJS/TEN overlap, and >30% of BSA for TEN by definition[27] (Figs 4 and 5). As previously mentioned, there are a few exceptions in which "TEN without spots" exhibit >10% epidermal detachment on a large patch of erythema without preceding confluent purpuric macules or atypical flat target lesions. They most often begin with a prodrome of fever, malaise, anorexia, pharyngitis, headache, and rash, which may be morbilliform, defined as a fine, discrete maculopapular exanthem, or consist of atypical targetoid macules.[16,32-35] Flaccid bullae, skin erosions, and painful inflammation and ulceration in the oral cavity

Fig 7. Toxic epidermal necrosis. Severe oral mucositis that may result in dysphagia and dysphasia.

comprise the major signs, which develop over a period of 1 day to 2 weeks[33] (Fig 6). The skin is often tender to the touch, with lateral pressure producing shedding of the epidermis from the dermis, known as the Nikolsky sign,[36,37] which is also seen in patients with autoimmune bullous skin disease.[29] Painful inflammation and ulceration of the mucosal surfaces occurs in 87% to 100% of cases of TEN, with oral involvement in 71% to 100% (Fig 7), ocular involvement in 50% to 78%, genital involvement in 40% to 63%, and lesions at all 3 sites occurring in 34% to 50% of patients.[10,12,33,38,39] Reepithelialization in TEN begins within several days, with slower healing occurring at mucosal sites and in areas of pressure, maceration, or infection.[12,33,38]

SYSTEMIC MANIFESTATIONS

- **Toxic epidermal necrolysis is associated with erosion, necrosis, and severe dysfunction of the ocular, pulmonary, cardiovascular, gastrointestinal, and renal systems, as well as aberrations in the hematopoietic system**

TEN has been described as acute skin failure,[40] but multiple organ systems are also involved, with erosion and necrosis occurring in the conjunctivae, trachea, bronchi, gut, and kidney.[35,41-45] We therefore view TEN as an extensive sloughing of both the internal and external mucocutaneous membranes. Acute renal failure with increased microalbuminuria and renal tubular enzymes in the urine, which is suggestive of glomerular structure alteration and proximal tubular damage, has been identified.[41,46] However, no direct correlation has been found between the extent of TEN and microalbuminuria or enzymuria. The nephrotoxic properties of the cytokines implicated in the pathogenesis of TEN have been linked to the destruction of the tubular cells, glomerular filtration barrier, and mesangial cells.[41] In the absence of histologic data, other etiologies of renal dysfunction cannot be excluded, such as stress, hypovolemia, and low cardiac output. Pulmonary involvement causing adult respiratory distress syndrome, bronchiolitis obliterans, and subcutaneous emphysema has been documented.[44,47] A prospective clinical study of pulmonary complications in patients with TEN found that 25% of them developed early pulmonary dysfunction, as evidenced by hypoxemia (mean PO_2 of 59 ± 8 mm Hg), dyspnea, and bronchial mucosal sloughing on fiberoptic bronchoscopy. Although pulmonary dysfunction is often not detectable on a chest radiograph at the time of admission, subsequent series have revealed interstitial infiltrates.[48] Anemia, leukopenia, and hepatitis are commonly seen. Severe abdominal pain, diarrhea, transiently elevated liver enzymes, hypoalbuminemia, hyponatremia, encephalopathy, and myocarditis may also be present.[12,35,38,47,49]

ETIOLOGY

- **The majority of cases of toxic epidermal necrosis are the result of a hypersensitivity reaction to a drug**
- **Other causative agents include *Mycoplasma pneumonia*, dengue virus, cytomegalovirus, and contrast medium**

Although TEN has occurred after measles-mumps-rubella vaccination,[50,51] infection with *Mycoplasma pneumonia*[7,52,53] and dengue virus,[54] reactivation of cytomegalovirus,[55] and after the administration of contrast agents,[56,57] the overwhelming number of cases are related to drug hypersensitivity. In the European Severe Cutaneous Adverse Reaction (EuroSCAR) study surveillance of medications, a number of them were classified as being high risk: nevirapine, lamotrigine, carbamazepine, phenytoin, phenobarbital, cotrimoxazole and other antiinfective sulfonamides, sulfasalazine, allopurinol, and oxicam nonsteroidal antiinflammatory agents (Table I).[58] Roujeau et al[28] previously implicated many of these drugs in TEN and also noted an increased risk with aminopenicillins, cephalosporins, and quinolones. TEN usually occurs between 7 days and 8 weeks after drug ingestion, with a mean time of onset ranging from 6 days to 2 weeks.[7,12,28,37,59] Upon readministration of the implicated drug, TEN may develop within hours.[59]

Sassolas et al[60] developed an algorithm of drug causality for epidermal necrolysis (ALDEN) and reassessed the risk–benefit profiles of all cases enrolled in the EuroSCAR study (Table II). ALDEN assigned each drug a score from −1 to 10 based on 6 parameters: (1) the time delay from initial drug intake to onset of reaction; (2) the probability of drug presence in the body on the index day; (3) a previous history of adverse reaction to the same

Table I. Drugs at risk for causing toxic epidermal necrolysis*

Nevirapine
Lamotrigine
Carbamazepine
Phenytoin
Phenobarbital
Cotrimoxazole and other antiinfective sulfonamides
Sulfasalazine
Allopurinol
Oxicam nonsteroidal antiinflammatory drugs
Aminopenicillins
Cephalosporins
Quinolones

*Data from Roujeau et al[28] and Mockenhaupt et al.[58]

Table II. Drugs that are commonly associated with a risk of Stevens–Johnson syndrome/toxic epidermal necrolysis based on the algorithm for drug causality for epidermal necrolysis*

Allopurinol	Minocycline	Phenytoin
Carbamazepine†	Nevirapine	Sulfasalazine
Fluoroquinolones	Nonsteroidal antiinflammatory drugs	Trimethoprim-sulfamethoxazole
Lamotrigine	Phenobarbital	

*Data from Dobrosavlijevic et al,[50] Mockenhaupt et al,[58] Guillaume et al,[59] and Sassolas et al.[60]
†Human leukocyte antigen-B*1502 pharmacogenetic screening recommended for patients of Han Chinese/Southeast Asian ancestry.

drug; (4) the presence of the drug beyond the progression phase of the disease; (5) the drug notoriety based on previous results of the SCAR study; and (6) the presence or absence of other etiologic causes. The score is categorized as very probable (≥ 6), probable (4-5), possible (2-3), unlikely (0-1), and very unlikely (<0; Table III).

There was an overall accordance between the results of ALDEN and the case control analysis of the EuroSCAR study.[58,60] ALDEN may be a practical, objective tool that allows immediate causality assessment of drugs in SJS and TEN without the need for expensive case control analysis in the future. ALDEN has practical implications not only for the clinicians, but also for pharmaceutical companies, regulatory agencies, and research institutes.

IMMUNOPATHOGENESIS

- **Toxic epidermal necrolysis is a T cell–mediated disease with $CD8^+$ cells acting as the major mediator of keratinocyte death**

Table III. Algorithm for drug causality for epidermal necrolysis*

Category and description	Score
Period between the drug intake and onset of reaction (index day)	
5-28 days	3
29-56 days	2
1-4 days	1
>56 days	−1
Drug started on index day	−3
With previous history of adverse reaction, 1-4 days	3
With previous history of adverse reaction, 5-56 days	1
Presence of drug in the body on index day	
Stopped on the index day or within 5 times the elimination half-life before the index day	0
Stopped at a time point before the index day by >5 times the elimination half-life†	−1
Stopped at a time point before the index day by >5 times the elimination half-life	−3
Previous history of adverse reaction	
SJS/TEN from same drug	4
SJS/TEN from similar drug	2
Other reaction from similar drug	1
No history of exposure to the drug	0
Previous use without any reaction	−2
Continued drug use beyond index day	
Stopped or unknown	0
Continued	−2
Drug notoriety derived from previous results of the SCAR study‡	
"High risk"	3
"Lower risk"	2
"Under surveillance"	1

‡Data from Hung et al[46] and Yamane et al.[47]

- **Two theories have emerged to explain the activation of $CD8^+$ cells: the pharmacologic interaction of drugs with the immune system and the pro-hapten theory**
- **Particular human leukocyte antigen allotypes are involved in the pathogenesis of toxic epidermal necrolysis and increase the risk of experiencing this drug reaction**

TEN is a T cell—mediated disease with a preponderance of $CD8^+$ lymphocytes found in blister fluid[61-63] and in perivascular superficial dermis with evidence of epidermal exocytosis.[64,65] $CD8^+$ cytotoxic T cells, along with natural killer (NK) cells, are theorized to be the major inducers of keratinocyte apoptosis.[61-63] Despite the central role of $CD8^+$ cells, $CD4^+$ cells and cells of the innate immune system ($CD3^-CD56^+$ NK cells, dendritic cells, mast cells, $CD14^+CD16^+$ monocytes, granulocytes, and NK/T cells) also play a role in TEN.[66] However, the mere presence of a cell type in lesional skin does not by itself imply causality. The complex interplay between many of these cells makes it difficult to distinguish the primary culprit. Caproni et al[65] studied the cellular infiltrate in skin samples from patients with TEN and found a strong representation of CD40 ligand (CD40L) staining cells in the dermis with some of the CD40L cells infiltrating the epidermis. CD40L is a molecule expressed on the surface of activated $CD4^+$ cells and is an important costimulator of macrophages, dendritic cells, B cells, and epithelial cells, leading to the release of tumor necrosis factor—alfa (TNF-α), nitric oxide (NO), interleukin 8 (IL-8), and cell adhesion molecules. Caproni et al[67] also found soluble CD40L (sCD40L) elevated in the sera of patients with TEN, raising the possibility that sCD40L could be used as a marker of TEN/SJS. The $CD4^+$ cells in the dermis and epidermis of patients with TEN were documented to have no Th1 or Th2 polarization, with equal concentrations of Th1-related cytokines and Th2-related cytokines found in the skin samples. Th1 helper T cells secrete IL-2 and interferon-gamma (INFγ) and are responsible for the activation of macrophages and cytotoxic T cells. Th2 helper T cells secrete IL-4, IL-5, IL-10, and IL-13 and are responsible for eosinophil activation and B cell class switching to immunoglobulin E antibodies.[68] Although little is known about the Th2 response in TEN, it could be an attempt to downregulate the Th1 response and limit the damage caused by cytolytic T cells.[69]

Macrophages, neutrophils, and NK cells have been implicated in TEN, with some studies reporting macrophages as the most abundant cell type found in cutaneous samples.[65,70] Tohyama et al[71] noted the presence of numerous $CD14^+CD16^+$ monocyte lineage cells infiltrating the epidermis and the dermoepidermal junction of SJS/TEN skin lesions, which may enhance the proliferation and cytotoxicity of $CD8^+$ T cells via the CD137/CD137L system. The monocyte/macrophages may contribute to the apoptotic process via production of TNF-α, TNF-related apoptosis-inducing ligand, and TNF-related weak apoptosis inducer.[72] Neutrophils and factor $XIIIa^+$ dendritic cells have also been found in these skin samples,[65,70,73] but their role in TEN has not been clarified. NK cells have been found in the blister fluid along with highly toxic cytolytic T cells that express the NK receptor CD56. These 2 cell types are understood to be the main inducers of keratinocyte apoptosis.[62,63] The importance of $CD8^+$ T lymphocytes in TEN pathogenesis has been reinforced recently with the advent of a novel, human-oriented TEN mouse model. This new mouse model unlocks vast potential in diagnostic and therapeutic research.[74]

The mechanism of T cell activation in TEN remains under investigation. There are 2 predominant theories: the pharmacologic interaction of drugs with the immune system (p-i concept) and the pro-hapten concept. In the pro-hapten concept, drugs are digested into metabolites that bind covalently to cellular peptides, creating an immunogenic molecule capable of stimulating the breadth of the immune system. The p-i concept asserts that a drug can stimulate the immune system by noncovalently binding directly to the major histocompatibility complex (MHC) I and the T-cell receptor (TCR), much like the drug would bind to its pharmacologic target. In this model, the drug's affinity for the MHC I molecule and TCR would induce only a T cell response, which would account for the lack of B cell proliferation seen in TEN.[75] Sulfamethoxazole (SMX) and abacavir have been studied in an effort to determine which theory is responsible for T cell activation; however, no clear answer has emerged. Castrejon et al[76] took lymphocytes from patients with known hypersensitivity reactions to SMX, including 1 patient who experienced SJS, and found that SMX-induced clonal expansion of T cells could occur independent of antigen presenting cells (APCs), confirming studies showing that SMX can directly bind to the MHC I molecule and TCR to activate T cells.[77,78] This study also found that SMX metabolites were unable to induce T cell proliferation when the APCs were incubated with glutathione and glutaraldehyde, known inhibitors of antigen presentation, supporting the idea that SMX can stimulate T cells by acting as a pro-hapten.[76]

Recent work on abacavir-induced hypersensitivity reactions revealed that $CD8^+$ cell proliferation was prevented by inhibition of antigen processing by APCs and by the use of APCs with deficiencies in the MHC antigen presentation pathway, favoring the role of the pro-hapten concept in abacavir-induced T cell activation.[79] Additional research on drug-induced T cell activation is necessary to determine whether the p-i concept, the pro-hapten concept, or both are responsible for T cell activation in TEN.

Many studies have revealed the genetic relationship between MHC I allotype and drug hypersensitivity reactions. In Han Chinese patients with TEN/SJS, a strong association exists between aromatic antiepileptic agents, including carbamazepine, phenytoin, oxcarbazapine, and lamotrigine, and the MHC I allotype human leukocyte antigen (HLA)-B*1502[80-82] as well as between allopurinol and HLA-B*5801.[83] The association between HLA-B*1502 and carbamazepine-induced TEN/SJS also exists in Thai,[84,85] Malaysian,[86] and South Indian[87] populations, but not in Japanese, Korean,[88-90] or European[91] populations, while the association between allopurinol and HLA-B*5801 is also found in patients of European descent.[92] In addition, a correlation was also shown between HLA-B*5701 and abacavir-induced hypersensitivity reactions[93,94] and between carbamazepine-induced hypersensitivity reactions and HLA-A*3101 in Europeans.[95]

The strong association between TEN and certain MHC allotypes has led to the speculation that these allotypes are not simply genetic markers, but are involved in the pathogenesis of TEN.[96] This idea was explored by investigating the role of HLA-B*5701 in the pathogenesis of abacavir drug hypersensitivity reaction. In this study, peripheral blood mononuclear cells (PBMCs) from abacavir-naïve patients with the HLA-B*5701 allotype were found to activate $CD8^+$ but not $CD4^+$ cells when incubated with abacavir. In contrast, none of the PBMCs from abacavir-naïve patients without the HLA-B*5701 allotype elicited T cell activation. In addition, alteration of a single serine residue at position 116 in the F pocket of the HLA-B*5701 allotype prevented the abacavir-induced $CD8^+$ cell activation. These results show the $CD8^+$ cell–specific activation by abacavir, the importance of the MHC I allotype in the pathogenesis of drug hypersensitivity reactions, and the specificity between abacavir and a particular HLA allotype. It is unclear whether the antigen that binds to the F pocket of HLA-B*5701 is abacavir itself, a metabolite of abacavir, or a hapten–peptide adduct.[79]

ETIOLOGY OF APOPTOSIS

- **Apoptosis is the cause of keratinocyte death, with $CD8^+$ cell exocytosis of granzyme B/perforin and granulysin implicated as the primary mediators of apoptosis**
- **Soluble Fas ligand, nitric oxide (NO), and tumor necrosis factor–alfa also contribute to keratinocyte apoptosis**

While a complete understanding of the pathophysiology of TEN remains elusive, recent studies have expanded our knowledge of the mechanisms underlying epidermal death. Apoptosis was found to be the cause of cell death in TEN,[97] with granulysin most recently implicated as the pivotal trigger of the apoptosis. Other pathogenic factors include Fas ligand (FasL), TNF-α, perforin/granzyme B, and NO.

A strong case has been evinced for granulysin as the predominant cause of keratinocyte apoptosis in TEN.[98] Granulysin is a molecule found in the cytotoxic granules, along with granzyme B and perforin, of $CD8^+$, NK, and NK/T cells and is important as a tumoricidal and bactericidal agent. Upon activation of the cytolytic or NK cell, granulysin is exocytosed and appears to "scissor through" the membranes of target cells, causing ionic instability, which leads to mitochondrial damage and cell apoptosis.[99] In a study on granulysin and TEN, Chung et al[98] compared the gene expression of blister fluid cells with PBMCs and found a 10- to 20-fold increase in blister cell expression of granulysin, an eightfold increase in granzyme B, a threefold increase in perforin, and a twofold increase in serum FasL (sFasL). Measurement of granulysin levels in the blister fluid followed the same pattern, revealing a 2- to 4-orders of magnitude increase in granulysin compared with perforin, granzyme B, and sFasL, with granulysin levels correlating with the disease severity. Immunohistochemistry of skin biopsy specimens found intense granulysin staining of the edges of the necrotic epidermis in patients with TEN, with only weak granulysin staining in patients with a drug-induced maculopapular eruption. When the cytotoxicity of the purified recombinant forms of the above proteins was assessed using the concentrations found in the blister fluid, only granulysin elicited significant apoptosis of keratinocytes, and was able to do so at concentrations much lower than sFasL, perforin, or granzyme B found in the blister fluid.[100] In the final portion of this study, Chung et al[98] intradermally injected purified recombinant granulysin and granzyme B into separate rats and found that skin necrosis and blistering, reminiscent of TEN, occurred only in the rats injected with granulysin. Granulysin was also found to exhibit cytotoxicity in a dose-dependent fashion. Abe et al[101] then showed that serum levels of granulysin were increased in 4 of 5 patients with TEN/SJS before skin detachment or the development of mucosal lesions, and that granulysin levels were increased in only 1 of 24 patients with ordinary drug-induced skin reactions. Together, these studies strongly argue for granulysin as an important inducer of apoptosis in TEN and as a promising marker for early diagnosis.[98,101]

FasL is a transmembrane protein from the TNF family that is expressed on the surface of cytotoxic

T cells, NK cells, immune privileged cells of the testes and eye, and keratinocytes. When cytotoxic T cells are activated, FasL is expressed on their surface and binds to its receptor on target cells, which activates intracellular caspases, leading to the controlled destruction of the target cell. In addition, FasL can be cleaved from its cell membrane by metalloproteinases, producing a soluble from of FasL, which retains the capacity to bind to the Fas receptor and trigger apoptosis.[102,103] Multiple studies have established the importance of the Fas—FasL pathway in the pathogenesis of TEN.[104-107]

Granzyme B and perforin have been shown to play a role in TEN keratinocyte and endothelial apoptosis. Cytolytic T cells, when activated by a target cell, exocytose perforin and granzyme B molecules, which create channels in the target cell membrane and activate caspases, respectively, causing cell apoptosis.[108] In a study of patients with TEN, mononuclear cells from the blister fluid were shown to induce apoptosis in the presence of anti-Fas antibodies, but not in the presence of inhibitors of perforin/granzyme B, implicating perforin/granzyme B as the cause of the apoptosis.[61,62] The level of these molecules was also found to be correlated with severity of the drug reaction, suggesting that perforin/granzyme B testing could be used to differentiate TEN from more mild drug eruptions.[109] Recent studies on biopsy specimens from patients with drug-induced eruptions, including TEN, reported endothelial apoptosis, with immunohistochemical staining revealing granzyme B and TNF-α around the dermal vessels. Although FasL was not found in the biopsy specimens, sFasL could not be excluded as a cause of the endothelial apoptosis, because the biopsy specimens were drawn 2 to 4 days after the drug eruption, when sFasL levels have been shown to precipitously decline.[110,111]

Other cytokines and molecules, such as TNF-α and NO, have been implicated in the apoptosis of TEN. TNF-α has been shown to activate the "death receptor" TNF-R1, causing caspase activation and cell death, and TNF-α is elevated in the blister fluid,[100] skin,[112] and sera[92] of patients with TEN. Although increased TNF-α is found in TEN, its role remains unclear. In addition to causing apoptosis, TNF-α is also known to activate the antiapoptotic nuclear factor-kappaB (NF-κB) pathway,[113] leading to speculation that it functions mainly in a protective role in TEN.[100,113] This idea may explain the increased mortality found in TEN patients treated with the anti—TNF-α agent thalidomide. Although the increased mortality may have been caused by a paradoxical increase in TNF-α, the specter that TNF-α mainly acts in an antiapoptotic capacity in TEN could not be excluded.[114] NO has been implicated in apoptosis, and is believed to stimulate the activity of caspases through the action of p53.[115] Prebullous skin samples of patients with TEN/SJS have shown increased levels of inducible NO synthase (iNOS).[116] IFN-α and TNF-α secreted by activated T cells have been shown to induce iNOS expression, NO-dependent FasL upregulation, and ultimately apoptosis in keratinocytes; this implicates IFN-α, TNF-α, and iNOS as the potential molecular bridge between the drug-specific immune response on one side and the expression of proapoptotic molecules on the other.[117] The combination of TNF-α, NO, and the ensuing elevation of reactive oxygen species may also contribute to resultant oxidative stress and the disruption of the intracellular machinery and membrane, which leads to apoptosis.[118]

In summary, TEN is initiated either by noncovalent, direct interaction of a drug with a specific MHC I allotype or by covalent binding of a drug metabolite to a cellular peptide, forming an immunogenic molecule. $CD8^+$ cells, activated by keratinocytes and APCs expressing specific MHC I and antigen, release INF-γ, causing the activation of macrophages and keratinocytes and perforin/granzyme B and granulysin. The activated macrophages and keratinocytes upregulate MHC I and release TNF-α and chemoattractants, while granulysin and perforin/granzyme B diffuse through the epidermis, acting as the major inducers of apoptosis. Activated $CD8^+$ cells and keratinocytes also upregulate FasL, which, along with TNF-α, induces additional apoptosis. Neutrophils, drawn to the skin by chemoattractants, and NO, released from activated keratinocytes, would seem to play a minor role in apoptosis. The presence of Th2 cytokines most likely indicates an attempt to dampen the inflammatory response and to curtail the activation and proliferation of cytotoxic T cells.

CONCLUSION

TEN is a life-threatening, usually drug-induced mucocutaneous reaction that is characterized by flaccid bullae and cutaneous and mucosal epithelial denudation. Drug-induced $CD8^+$ cell activation is highly specific for particular HLA allotypes, placing certain populations at a greater risk for developing TEN. While sFasL, TNF-α, and granzyme B/perforin are important in the pathogenesis of TEN, granulysin appears to be the main mediator of the apoptosis. The importance of this molecule in TEN should continue to be elucidated with the hope of spurring new treatment options to

lower the morbidity and mortality associated with this deadly condition.
